Abstract

This paper deals with the integer frequency offset (IFO) estimation for orthogonal frequency division multiplexing (OFDM)-based digital video broadcasting-terrestrial (DVB-T) systems. In the conventional scheme, the decision variable is based on the limited number of the correlations and ratios of pilots of the received samples, and thus, the decision variable contains only a small portion of the signal energy, resulting in performance degradation. In this paper, we propose two novel IFO estimation schemes combining the correlations and ratios of pilots of the received samples efficiently. Numerical results demonstrate that the proposed schemes provide a better performance compared with that of the conventional scheme in terms of the correct estimation probability.

Keywords: Digital video broadcasting-terrestrial (DVB-T), estimation, integer frequency offset (IFO), orthogonal frequency division multiplexing (OFDM), pilot.

1 Introduction

Recently, driven by the demand for high quality mobile broadcasting services, digital video broadcasting-terrestrial (DVB-T) systems have been highlighted due to its high data rate [1]-[3]. DVB-T systems are able to maintain its high data rate by employing an orthogonal frequency division multiplexing (OFDM) as the modulation scheme [4], [5]. However, the frequency offset (FO) occurred by the mismatch between the oscillators in the transmitter and receiver or Doppler frequency severely degrades the overall performance of the OFDM-based systems
Thus, the FO estimation and compensation processes are essential for the reliable DVB-T systems. The FO normalized to the subcarrier spacing of the OFDM symbol can be divided into the integer and fractional parts, which bring on a shift of the subcarrier indices of the OFDM symbol and an intercarrier interference, respectively. In this paper, we focus on the integer FO (IFO) estimation for OFDM-based DVB-T systems.

Several IFO estimation schemes have been proposed for the DVB-T systems [8], [9]. In [8], the IFO is estimated using the decision variable generated by combining the correlations and ratios of pilots of the received samples with the same subcarrier indices of two consecutive OFDM symbols. In order to improve the IFO estimation performance, the scheme in [9] uses not only the correlations in [8], but also some additional correlations between the received samples in each OFDM symbol to form the decision variable. However, the decision variables in [8], [9] are based on the limited number of the correlations and ratios of pilots, and thus, the decision variables contain only a small portion of the signal energy, resulting in performance degradation.

In this paper, thus, we propose two novel IFO estimation schemes combining the correlations and ratios of pilots of the received samples efficiently. In the proposed scheme I, all possible correlations and ratios of pilots of the received samples are combined to form the decision variable. In the proposed scheme II, the number of combinations between the correlations and ratios of pilots are combined efficiently to form a decision variable using a distance parameter considering the influence of the channel. Numerical results demonstrate that the proposed schemes provide a better performance compared with that of the conventional scheme in [9] in terms of the correct estimation probability.

2 System Model

DVB-T systems operate in 2K or 8K mode, depending on the total number of the subcarriers. In this paper, we consider DVB-T systems with 2K mode, where 1705 subcarriers among 2048 total subcarriers are used to transmit data, 45 continual pilots (CPs), and 142 or 143 scattered pilots (SPs). Fig. 1 describes the pilot arrangement in DVB-T systems with 2K mode, where \( K_{\text{min}} \) and \( K_{\text{max}} \) are the smallest and largest subcarrier indices of the active subcarriers that transmit the complex valued symbols, respectively [4]. The subcarrier indices of the CPs in an OFDM symbol are fixed and their subcarrier indices are the same for all OFDM symbols, on the other hand, the SPs are periodically inserted every twelve subcarriers in an OFDM symbol and their locations are periodic for every four OFDM symbols.
Efficient Integer Frequency Offset Estimation Schemes for DVB-T Systems

Figure 1: Pilot arrangement in DVB-T systems with 2K mode.

The \( n \) th sample of the \( l \) th OFDM symbol is generated by taking the inverse fast Fourier transform (IFFT) and can be expressed as

\[
x_l(n) = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} X_l(k) e^{j2\pi kn/N}, \quad \text{for} \quad l = 0, 1, \cdots, \quad \text{and} \quad 0 \leq n \leq N - 1,
\]  

(1)

where \( N \) is the size of the IFFT, \( k \) is the subcarrier index, and \( X_l(k) \) is a pilot or data transmitted through the \( k \) th subcarrier of the \( l \) th OFDM symbol. After the guard interval is inserted, the output sequence including the guard interval is

\[
x_{l,g}(n) = x_l(n + N - N_g), \quad \text{for} \quad 0 \leq n \leq N + N_g - 1,
\]  

(2)

where \( N_g \) is the length of the guard interval and \((u)_v\) denotes the residue of \( u \) modulo \( v \). Then, the \( n \) th sample of the \( l \) th received OFDM symbol \( y_l(n) \) in the time domain is obtained as

\[
y_l(n) = e^{j2\pi n/N} \left[ h_l(n) \otimes x_{l,g}(n) \right] + w_l(n)
= s_l(n) + w_l(n), \quad \text{for} \quad 0 \leq n \leq N + N_g - 1,
\]  

(3)

where \( \Delta, h_l(n), \otimes, \) and \( w_l(n) \) denote the FO normalized to subcarrier spacing, the channel impulse response, the convolution operation, and an additive white Gaussian noise (AWGN) sample with zero mean and variance of \( \sigma_w^2 = \mathbb{E}\{w_l(n)^2\} \) respectively, where \( \mathbb{E}\{\cdot\} \) is the expectation operation. The signal-to-noise ratio (SNR) is defined as \( \sigma_s^2/\sigma_w^2 \) with \( \sigma_s^2 = \mathbb{E}\{s_l(n)^2\} \).

In the receiver, the guard interval is first removed, then, the estimation and compensation processes for the fractional FO (FFO) are generally performed before the IFO estimation [9]. Assuming the perfect estimation and compensation
for the FFO, the FFT output corresponding to the \( k \) th subcarrier of the \( l \) th received OFDM symbol is represented as

\[
Y_i(k) = H_i(k - \Delta_i)X_i(k - \Delta_i) + W_i(k),
\]

where \( \Delta_i \) is the IFO, \( H_i(k) \) is the channel response on the \( k \) th subcarrier of the \( l \) th OFDM symbol, and \( W_i(k) \) is the zero mean complex AWGN in the frequency domain. From (4), we can observe that the IFO introduces the shift of the subcarrier indices in the OFDM symbol.

The ratio between SP and CP of the \( l \) th OFDM symbol are defined as

\[
C_l(k) = \frac{X_i(k')}{X_i(k)}, \quad \text{for } k' \in S_{SP} \text{ and } k \in S_{CP},
\]

where \( S_{SP} \) and \( S_{CP} \) are the sets of the subcarrier indices of the SPs and CPs, respectively, \( k' \) is the index of the SP nearest to the CP with the index \( k \), and the ratio between CP of the \( l \) th OFDM symbol and CP of the \((l+1)\)th OFDM symbol are defined as

\[
D_l(k) = \frac{X_{i+1}(k)}{X_i(k)}, \quad \text{for } k \in S_{CP}.
\]

The value of \( C_l(k) \) is \(-1\) or \(1\) depending on the value of \( l \) and \( k \) and that of \( D_l(k) \) is \(1\) regardless of the value of \( l \) and \( k \).

Using the ratios between pilots, the conventional scheme in [9] obtains an estimate \( \hat{\Delta}_{l,\text{conv}} \) of \( \Delta_i \) as

\[
\hat{\Delta}_{l,\text{conv}} = \arg \max_{f_c \in \{f_c, \ldots, f_c\}} Z_{\text{conv}}(f_c)
\]

and

\[
Z_{\text{conv}}(f_c) = \text{Re} \left( \sum_{l=0}^{L-1} \sum_{k \in S_{SP}} U_l(k + f_c)C_l(k) + \sum_{l=0}^{L-2} \sum_{k \in S_{CP}} V_l(k + f_c)D_l(k) \right),
\]

where \( f_c \) is a trial value to estimate \( \Delta_i \), which is selected among the most reliable \( \alpha \) trial values obtained based on \( U_0(k + f)C_0(k) \), \( L \) is the number of the
OFDM symbols exploited to estimate \( \Delta_1 \), and \( U_i(k+f_c) \) and \( V_i(k+f_c) \) are defined as the correlations between the received samples \( Y_i(k+f_c)Y_i^*(k'+f_c) \) and \( Y_i(k+f_c)Y_{i+1}^*(k+f_c) \), respectively. When \( L=1 \), the decision variable \( Z_{\text{conv}}(f_c) \) of the conventional scheme changes as 
\[
Z_{\text{conv}}(f_c) = \text{Re} \left\{ \sum_{k \in \mathbb{C}} U_0(k+f_c)C_0(k) \right\},
\]
and when \( \alpha=1 \), the conventional scheme estimates the IFO as 
\[
\hat{\Delta}_{1,\text{conv}} = \arg \max_{|f| \leq N/2} \left\{ \text{Re} \left( \sum_{k \in \mathbb{C}} U_0(k+f)C_0(k) \right) \right\}.
\]
The conventional scheme would not have enough signal energy to perform reliable IFO estimation since the decision variable of the scheme is based on the number of CPs as shown in (7) and (8).

3 Proposed Schemes

In this section, we propose novel IFO estimation schemes using the decision variable generated by combining the correlations and ratios of pilots efficiently. First, we define the new ratio between pilots as 
\[
G_{q,m}(n,i) = \frac{X_{m}(i)}{X_{q}(n)}, \quad \text{for} \quad n \in S_{p_q} \quad \text{and} \quad i \in S_{p_m},
\]
where \( S_{p_q} \) and \( S_{p_m} \) are the sets of the subcarrier indices of the pilots in the \( q \) th and \( m \) th OFDM symbols, respectively. Then, using the new ratio \( G_{q,m}(n,i) \), we make the decision variable \( Z_{\text{prop1}}(f) \) as 
\[
Z_{\text{prop1}}(f) = \sum_{q=0}^{L-1} \sum_{m=0}^{L-1} \sum_{n \in S_{p_q}} \sum_{i \in S_{p_m}} G_{q,m}(n,i)Y_q(n+f)Y_m^*(i+f).
\]
Finally, the IFO can be estimated by 
\[
\hat{\Delta}_{1,\text{prop1}} = \arg \max_{|f| \leq N/2} \left\{ \text{Re}(Z_{\text{prop1}}(f)) \right\}.
\]
denoted by the proposed scheme I. As shown in (10), the proposed scheme I uses every possible combinations between the correlations and ratios of pilots, thus, it is expected that the proposed scheme I has a good estimation performance averaging the noise components out. However, in the frequency selective channel with small coherence bandwidth, the proposed scheme I would experience some performance degradation due to some correlations and ratios of pilots whose absolute difference of indices is larger than the coherence bandwidth.

Taking the coherence bandwidth of the channel into consideration, we define the modified ratio between pilots as

$$Q_{q,m}(n,i) = \frac{X_m(i)}{X_q(n)}, \quad \text{for } n \in S_{p_q} \text{ and } i \in S_{p_i}.$$  \hspace{1cm} (12)

which satisfies the condition $|n-i| \leq B$, where the distance parameter $B$ is not larger than the coherence bandwidth of the channel. Then, the modified decision variable $Z_{\text{prop II}}(f)$ is generated using the ratio in (12) as

$$Z_{\text{prop II}}(f) = \sum_{q=0}^{L-1} \sum_{m=0}^{L-1} \sum_{n \in S_{p_q}} \sum_{i \in S_{p_i}} Q_{q,m}(n,i) Y_q(n+f) Y_m^*(i+f),$$  \hspace{1cm} (13)

and we obtain the estimate for $\hat{\Delta}_i$ as

$$\hat{\Delta}_{i,\text{prop II}} = \arg \max_{|f| \leq N/2} \{\text{Re}(Z_{\text{prop II}}(f))\},$$  \hspace{1cm} (14)

which is referred to as the proposed scheme II.

Figs. 2 and 3 show the examples of the pilot combinations for correlations $Y_q(3+\Delta_i)Y_q^*(i+\Delta_i)$ and $Y_q(3+\Delta_i)Y_{q+1}^*(i+\Delta_i)$ ($1 \leq i \leq 10$) for proposed scheme I and II, respectively, when $B = 4$ and indices of the received OFDM symbols are $q$ and $(q+1)$. In Fig. 2, the number of the available correlations is 10, and they are combined with $G_{q,q}(3,i)$ and $G_{q,q+1}(3,i)$, meanwhile in Fig. 3, the number of the available correlations is 5, and they are combined with $G_{q,q}(3,i)$ and $Q_{q,q+1}(3,i)$. If the coherence bandwidth of the channel is sufficiently large, the decision variable of the proposed scheme I can fully exploit the pilot signal energy. However, if the coherence bandwidth of the channel is small, the decision variable of the proposed scheme I includes undesirable correlations between the
Efficient Integer Frequency Offset Estimation Schemes for DVB-T Systems

pilots whose distance is larger than the coherence bandwidth, which would lower the signal energy of the decision variable, thus in this case, the proposed scheme II would be preferred to the proposed scheme I.

\[
Y_q^* (3 + \Delta_i) Y_q^* (i + \Delta_i) \quad \text{and} \quad Y_q^* (3 + \Delta_i) Y_{q+1}^* (i + \Delta_i) \quad (1 \leq i \leq 10)
\]

for the proposed scheme I when indices of the received OFDM symbols are \( q \) and \( (q + 1) \).

\[
Y_q^* (3 + \Delta_i) Y_q^* (i + \Delta_i) \quad \text{and} \quad Y_q^* (3 + \Delta_i) Y_{q+1}^* (i + \Delta_i) \quad (1 \leq i \leq 10)
\]

for the proposed scheme II when \( B = 4 \) and indices of the received OFDM symbols are \( q \) and \( (q + 1) \).

4 Numerical Results

In this section, the proposed schemes are compared with the conventional scheme in [9] in terms of the correct estimation probability defined as the probability that the estimate IFO is the same as \( \Delta_i \). We consider DVB-T systems with 2K mode. The parameters are as follows: \( \alpha = N = 2048 \), \( L = 2 \), \( N_y = 256 \), and \( B = 12 \). For simulations, we employ the multipath fading channel with 9 paths. The distance between paths is set to 10 samples and the amplitude of each path has a Rayleigh distribution with average power \( E\{A_j^2\} = \exp(-0.8j) \) where \( j \) is the index of the path \( (0 \leq j \leq 8) \). The coherence bandwidth of the channel for the simulation is approximately 34 (normalized to subcarrier spacing) [10].
Fig. 4 shows the correct estimation probabilities of the conventional and two proposed schemes in the AWGN channel model whose coherence bandwidth is infinity. As shown in Fig. 4, the proposed schemes outperform the conventional scheme. Especially, the correct estimation probability of the proposed scheme I is close to 1 at low SNRs such as −18 and −15 dBs, since the proposed scheme I fully exploits the pilot signal energy. Otherwise, the proposed scheme II has some performance degradation compared with that of the proposed scheme I, however, the proposed scheme II has better performance than the conventional scheme based on its efficient combinations.
Efficient Integer Frequency Offset Estimation Schemes for DVB-T Systems

Fig. 5 shows the correct estimation probabilities of the conventional and two proposed schemes in the multipath fading channel model whose coherence bandwidth size is 34. Unlike in Fig. 4, it is shown that the performances of the proposed scheme I has worse performance than the conventional scheme and proposed scheme II in the SNR range above $-4 \, \text{dB}$ and $-10 \, \text{dB}$, respectively. This is due to the fact that the influence of the noise becomes larger than that of the channel as the SNR decreases, thus, the performance of the proposed scheme I is the best in the low SNR range. On the other hand, as the SNR increases, the influence of the channel becomes larger than that of the noise, thus, the performance of the proposed scheme I becomes worse than those of other schemes. The proposed scheme II has the best performance above the SNR value of $-10 \, \text{dB}$, since the proposed scheme II considers the influence of the channel by using the distance parameter $B$.

5 Conclusion

In this paper, we have proposed novel IFO estimation schemes with the decision variables generated by combining the correlations and ratios of pilots efficiently for OFDM-based DVB-T systems. In the proposed scheme I, the decision variable is formed by combining all available correlations and ratios of pilots, on other hand, in the proposed scheme II, the number of combinations between the correlations and ratios of pilots are combined efficiently to form a decision variable using a distance parameter considering the influence of the channel. From the numerical results, we have confirmed that the proposed schemes provide a better performance compared with that of the conventional scheme in terms of the correct estimation probability. When the coherence bandwidth of the channel is sufficiently large, the proposed scheme I has the best performance, on the other hand, when the coherence bandwidth of the channel is small, the proposed scheme II shows the best performance by using the distance parameter at high SNR range.
